

The Properties of Molecular Hydrogen toward the Orion Belt Stars from Observations by the Interstellar Medium Absorption Profile Spectrograph

Edward B. Jenkins¹, Przemysław R. Woźniak¹, Ulysses J. Sofia^{2,3}, George Sonneborn⁴, and Todd M. Tripp¹

ABSTRACT

Absorption features from the Lyman and Werner bands of interstellar molecular hydrogen were recorded by the Interstellar Medium Absorption Profile Spectrograph (IMAPS) at $\lambda/\Delta\lambda = 80,000$ in the spectra of δ Ori A and ϵ Ori. The objective was to find and study more examples of an unusual phenomenon found for one of the velocity components of H_2 in the spectrum of ζ Ori by Jenkins & Peimbert (1997). Specifically, they detected a gradual shift in velocity and broadening for features arising from progressively higher rotational excitations J . This effect appears to be absent in the spectra of both δ and ϵ Ori, which are only a few degrees away in the sky from ζ Ori. The absence of atomic material at a large negative velocity in the spectra of δ and ϵ Ori (and its presence in ζ Ori) supports a proposal by Jenkins & Peimbert that the line of sight to ζ intercepts a bow shock facing away from us, perhaps created by the collision of wind-like material with some foreground obstruction. One edge of the molecular cloud complex Lynds 1630 is situated close to ζ Ori in the sky, but we present some evidence that seems to indicate that the cloud is more distant, in which case it could not serve as the obstruction. However it is possible that the outermost extension of a high-speed jet from a star forming within the cloud can explain the high-velocity material and the shock front created by it.

For both stars, the H_2 absorption features are separated into two velocity components. Total H_2 column densities toward δ and ϵ Ori are 5.5×10^{14} and $1.9 \times 10^{16} \text{cm}^{-2}$, respectively. When these values are compared to the

column densities of H I, the fractions of H atoms bound in molecular form $2N(\text{H}_2)/[2N(\text{H}_2) + N(\text{H I})] = 7 \times 10^{-6}$ for δ and 1.3×10^{-4} for ϵ . The rotation temperatures of the molecules with $J > 2$ toward ϵ Ori indicate that the gas is in the general vicinity of the stars that emit UV fluxes capable of rotationally pumping the molecules. For the strongest component of H_2 toward δ Ori, the pumping rate is lower and consistent with a general UV flux level in the plane of the Galaxy.

1. Introduction

The absorption bands of the Lyman and Werner systems arising from the ground vibrational state of H_2 provide a rich array of electronic transitions from different rotational levels. It is often true that these are the most conspicuous and plentiful features in the spectra of early-type stars below about 1100Å (Morton 1975; Jenkins et al. 1989; Snow, Allen, & Polidan 1990). In the interstellar medium, the rotational excitation of molecular hydrogen is driven by a number of processes, such as collisional excitation and de-excitation, optical pumping by starlight, and the introduction of newly formed molecules. For this reason, the relative rotational populations of H_2 have been used to gain insights on the characteristic molecule formation (and destruction) rates, temperatures, and densities in the H_2 -bearing clouds (Spitzer & Cochran 1973; Spitzer et al. 1973; Spitzer, Cochran, & Hirshfeld 1974; Spitzer & Zweibel 1974; Jura 1975a, b; Morton & Dinerstein 1976; Shull 1977, 1979; Shull & York 1977). The UV data provide critical insights on the character of H_2 that are useful to other kinds of observations and our current understanding of how various environmental factors influence the rates of molecule formation and destruction (Shull & Beckwith 1982).

In some cases, initial studies with the *Copernicus* satellite revealed changes in the widths of the profiles for absorption features arising from levels with different values of the rotational quantum number J (Spitzer & Cochran 1973; Spitzer, Cochran, & Hirshfeld 1974). More exacting analyses of high quality recordings of the H_2 profiles in several stars by Spitzer & Morton (1976) indicated that there were shifts in rotational temperatures for components with small changes in radial velocity, as one might expect for the gas behind shock fronts created by stellar winds. More recently, a significant improvement in the ability to study this phenomenon has come from the much better wavelength resolving power of

the Interstellar Medium Absorption Profile Spectrograph (IMAPS) (Jenkins et al. 1988), which has flown on both sounding rockets and orbital missions (Jenkins 1993, 1995; Jenkins et al. 1996).

Using data acquired by IMAPS on the ORFEUS-SPAS I mission launched on the STS-51 Space Shuttle flight in 1993, Jenkins & Peimbert (1997) discovered that one of the velocity components of H_2 in front of ζ Ori A showed small, progressive velocity offsets and profile broadenings as the rotation states increased from $J = 0$ to 5. They made the conjecture that this behavior could arise from H_2 forming in the collapsing column of partially ionized, cooling gas behind a nearly stationary bow shock facing away from us. This shock front was thought to be created by the abrupt deceleration of wind-like material from the star (or other stars nearby) as it collided with a dense cloud, perhaps similar to ones seen elsewhere in Orion that have comet-like tails facing away from prominent stars in the association (Bally et al. 1991; Cernicharo et al. 1992). This interpretation was supported by spectroscopic evidence for low-ionization material at -94 km s^{-1} (interpreted as the high speed material feeding the shock on its upstream side), and more highly ionized atoms at lower velocities (immediate post-shock gas at -36 km s^{-1}). These velocities, relative to the observed pileup of cold material at about 0 km s^{-1} , implied a low compression ratio of 2.6. Jenkins & Peimbert concluded that this outcome could be produced by an embedded magnetic field in the pre-shock material that is oriented nearly parallel to the flow.

The motivation of the present investigation of H_2 in front of the other two bright stars in the belt of the Orion constellation, δ Ori A and ϵ Ori, was to gather independent evidence on the phenomenon studied by Jenkins & Peimbert (1997) for ζ Ori A. Since there are indications that the three stars are within a large cavity containing x-ray emitting gas (Burrows et al. 1993) and enclosed by an expanding shell of cooler material (Reynolds & Ogden 1979) powered by either stellar winds (Castor, McCray, & Weaver 1975; Weaver et al. 1977) or by one or more explosive events (Cowie, Songaila, & York 1979), it was not unreasonable to expect that we could witness additional manifestations of the unusual behavior of H_2 . Tantalizing indications that a phenomenon similar to that found by Jenkins & Peimbert was occurring on the line of sight to δ Ori A were discussed by Spitzer & Morton (1976).

The two additional Orion Belt targets were observed by IMAPS on its second flight conducted in late 1996 aboard the ORFEUS-SPAS II mission on STS-80 (Hurwitz et al. 1998). We present here the results of our investigation of the absorption features arising from H_2 . The paper is organized as follows. The section on observations (§2) starts with a description of some fundamental properties of the two target stars (§2.1), δ and ϵ Ori,

along with ζ Ori A which is featured as a contrasting case in later discussions. The IMAPS instrument and some properties of the data that are relevant to our investigation are described in the next subsection (§2.2), and this is followed by a brief description of the exposures that were taken (§2.3). The section on analysis (§3) describes some general steps that were taken in the data reduction (§3.1), outlines some special procedures to register the velocities of features from H_2 in different J levels (§3.2), shows the results of an investigation to check on the relative f values of the weakest lines out of $J = 1, 2$ and 3 (§3.3), and ends with a description of how we constructed profiles of column density vs. velocity for each J level. The fundamental qualitative properties of the H_2 features in the spectra of δ and ϵ Ori are discussed in §4.1. The distributions of H_2 over different J levels are presented in §4.2, using the concept of a rotation temperature over specific J levels as a convenient way to describe the relative populations. We use these rotational temperatures to synthesize a few approximate conclusions about the strengths of the UV pumping fields. In the section that describes our interpretation of the results (§5), we note that the unusual shifts and broadening of the H_2 profiles for different J found by Jenkins & Peimbert (1997) seem to be correlated with the presence (for ζ Ori A) or absence (for δ and ϵ Ori) of high velocity gas (§5.1) or the possible proximity of ζ Ori to a dense cloud with a high rate of star formation inside (§5.2). Finally, in §6 we present a few remarks that pull together some of the concepts presented earlier and discuss their possible meanings.

2. Observations

2.1. Target Stars

The two stars studied in this paper, δ Ori A and ϵ Ori, have a separation in the sky of $1^\circ44$ and are members of the b subgroup defined by Blaauw (1964) within the Orion OB1 association. Later in this paper, we will be making comparisons with data recorded on an earlier IMAPS flight for ζ Ori A and reported by Jenkins & Peimbert (1997). This star is nearly on the same line as that joining δ and ϵ , but it is $1^\circ40$ degrees from ϵ (see Fig. 7). For the benefit of readers who wish to compare the H_2 results with other observations of interstellar material, the equatorial⁵ and galactic coordinates of the three stars are given in Table 1. Other important properties of these stars are also given in the table. All radial velocities reported in this paper are heliocentric; the table lists the numerical values that must be added to the heliocentric velocities to obtain those in the Local Standard of Rest.

⁵We have elected to use 1950 coordinates in Figs. 7 and 8 because nearly all of the maps of interstellar structures in the current literature use this coordinate system.

^b (Jenkins et al. 1999).

^c (Diplas & Savage 1994).

The Orion OB1 b subgroup is at a distance modulus of approximately 7.8 (360 pc) (Brown, de Geus, & de Zeeuw 1994) to 8.0 (400 pc) (Warren & Hesser 1978). The parallaxes measured by Hipparcos, 3.56 ± 0.83 mas for δ Ori A and 2.43 ± 0.91 mas for ϵ Ori (Perryman et al. 1997), are consistent with this range of distances. Both targets are bright, hot, and have a large projected rotation velocity (see Table 1), making them excellent UV light sources for viewing narrow interstellar absorption lines.

Since the instrument has no entrance slit, it is important to know if there are companion stars which could introduce contamination signals to the main spectra. There are two companions to δ Ori A with wide separations from the visual primary. One is a type B2V with a separation of $52''$ (HD36485), but its visual magnitude is fainter by 4.6, so its effect on the main spectrum is negligible. The other at $33''$ (BD–00 983B) has $V = 14$. Two bright components of δ Ori A were identified by Heintz (1980) and later confirmed by the speckle interferometry observations (McAlister & Hendry 1982). Recent determinations of their separation yield a value $0''.267$ (Lindgren et al. 1997; Mason et al. 1998), which is much smaller than the equivalent of our wavelength resolution projected onto the sky (about $10''$). Finally, the visual primary is a partially eclipsing, spectroscopic binary (Koch & Hrivnak 1981) with a period of 5.73 days (Harvey et al. 1987). Our other target, ϵ Ori, is a spectroscopic binary with also a visual companion that is $3'$ away and fainter by 8.7 magnitudes (Hoffleit & Jaschek 1982).

2.2. Instrument

Detailed descriptions of the IMAPS instrument and how it performs have been presented by Jenkins et al. (1988, 1996). Briefly, IMAPS is an objective-grating echelle spectrograph whose optical configuration is very simple, consisting of a mechanical collimator (to reject the off-axis light from stars other than the target), an echelle grating with a 63° blaze angle, a parabolic cross-disperser grating, and, at the focal point, an electron-bombarded, windowless, intensified CCD image sensor. The nominal wavelength coverage of $930 - 1150 \text{ \AA}$ is obtained in 4 sequential exposures that span the free spectral range of the echelle format at different angles of grating tilt. Spectra taken at different angles were not of uniform quality because they had different deviations off the optimum blaze angle of the echelle grating. This effect, combined with much lower reflection efficiencies of the gratings below about $1000 \text{ \AA}$, resulted in large changes in signal quality over different regions of the spectral format. Nevertheless, we were able to get good selections for lines out of various J levels (Tables 2 and 3), even after defining a quality threshold for acceptance at a reasonably high level. The instrument is capable of attaining

a wavelength resolution of order $R \equiv \lambda/\Delta\lambda = 2 \times 10^5$, but on this mission an out-of-focus condition resulted in $R \sim 8 \times 10^4$ and some overlap in energy between adjacent orders. The effective area of IMAPS for wavelengths greater than about 1000Å (where most of the H₂ features that we used are located) is about 3 cm².

There was a significant difference between the observations made on the ORFEUS-SPAS I and ORFEUS-SPAS II flights, i.e., those reported by Jenkins & Peimbert (1997) for ζ Ori A and those given in this paper, respectively. On the earlier flight, there was inadequate control of the humidity of the atmosphere inside the payload prior to launch. As a result, small water droplets formed on the hygroscopic (and easily damaged) KBr photocathode during the decompression and adiabatic cooling of the air inside the instrument that occurred during the initial phases of the Shuttle launch. As shown by Jenkins et al. (1996), all of the data recorded on the 1993 flight exhibited a blotchy pattern of efficiency variations caused by the damage to the photocathode. Within each blotch, the quantum efficiency was about 50% of the peak sensitivity in the unaffected regions. For the 1996 flight of IMAPS, more stringent precautions were taken to control the instrument’s internal atmosphere prior to launch. As a result, the damage was prevented and photocathode response was very high, and uniformly so over the entire format.

The photocathode damage on the first flight had both good and bad consequences. On the bad side, considerable effort during the reduction of the data was needed to make the required corrections for the variations. In some places, these corrections may not have been perfect, so unpredictable, systematic variations in intensity could arise. Also, the overall efficiency of the detector was somewhat less than it would have been otherwise. On the good side, the damage to the photocathode had a beneficial effect of providing an accurate indication of the detector’s geometrical mapping function. By correlating the apparent positions of the blotches in the data with a post-flight photograph of the damaged photocathode, accurate corrections for the distortion of the recorded spectral image could be implemented during data processing, with the end result of producing accurate wavelength determinations for all of the absorption features.

For the data from the second flight reported on here, we had excellent looking raw data frames but no information about the geometric distortions (aside from the bending of the orders – information which is of no use in understanding perturbations in the wavelength scale). It was clear that we could not use the mapping function from the previous flight for the δ and ϵ Ori data because there was a change in the stray magnetic fields from other systems (which affect the electron trajectories in the detector) from the first flight to the second. Thus, in short, for the ζ Ori data extraordinary measures were needed to correct for photometric errors, while wavelength derivations were relatively easy. For the δ and

ϵ Ori data the reverse was true: obtaining relative photometric information of good quality was straightforward, but special efforts were needed (described in §3.2) to obtain accurate radial velocities.

2.3. Exposures

The exposures for δ Ori A with a total integration time of 6064 s were spread over 3 sessions: 1996 November 22 01:39–02:15 UT, November 29 12:13–12:54 UT, and December 3 21:33–22:12 UT. The last session had all exposures taken at a single grating tilt to enhance the quality of the spectra at the very short wavelengths of the deuterium $L\delta$ and $L\epsilon$ transitions, used ultimately for the study of atomic D/H (Jenkins et al. 1999). An additional set of exposures was taken when the spacecraft was in a minimum drag configuration [to avoid a possible collision with another satellite (Hurwitz et al. 1998)], but the unusual aspect of the Sun created an unexpected change in thermal conditions that shifted the cross-disperser coverage to much longer wavelengths, ones that were inappropriate for studying the H_2 transitions. For ϵ Ori, a contiguous set of exposures was taken during a single orbit over the time interval November 29 04:33–05:20 UT, for a total exposure time of 2452 s. Sample portions of the spectra covering two H_2 absorption features are shown in Fig. 1.

3. Analysis

3.1. General Steps

To derive an approximate wavelength scale, dispersion constants for the various exposures were derived from the observed positions of H_2 features. However, we did not assume that lines out of different J levels or with very different strengths necessarily had the same apparent radial velocity. This analysis could be carried out because the H_2 lines are so plentiful (we used approximately twice as many lines as those selected for analysis and listed in Tables 2 and 3). We were able to create outcomes that were internally consistent to within about 0.87 km s^{-1} for δ Ori A and 0.62 km s^{-1} for ϵ Ori, as judged by the rms dispersion of apparent residual wavelength offsets for lines coming from any given J level. The lower rms dispersion of 0.5 km s^{-1} obtained by Jenkins & Peimbert (1997) reflected the better control they had over their wavelength scales, as discussed in §2.2. An important objective of our investigation was to detect any shifts in velocity across different J levels. For this purpose, we devised a more precise tuning of the wavelengths for just the H_2

Fig. 1.— Small samples of the spectra of δ Ori A and ϵ Ori recorded by IMAPS. The left-hand feature is the Lyman Band 3–0 P(1) line while the one on the right is the 3–0 R(2) line. The profiles of H_2 absorption are double peaked in the spectrum of ϵ Ori. A representative scale for radial velocities is shown in the upper panel.

profiles, so that we could register them with better accuracy. This procedure is described in §3.2 below.

Before extracting the spectra from the echelle orders, a distortion correction procedure was invoked to remap the images so that the orders were approximately straight and horizontal. Even though this was done, we found it necessary for the extraction program to determine the exact small residual vertical shifts (in the cross-dispersion direction) for each order as a function of horizontal position (along the echelle dispersion direction).

The distribution of energy across each order in the vertical direction varied with position, owing to small changes in aberrations in the image. Thus, in addition to characterizing the changes in the centers of the orders, we also measured their widths and how they varied with position. After the orders had been characterized, we performed an optimum extraction of spectral information using the formulae given by Jenkins et al. (1996). This method not only gives the best signal-to-noise ratio, but it also compensates for the small spillover of energy between adjacent orders. This is needed to prevent the appearance of spurious, ghost-like features that would ordinarily arise if a simple “dumb-slit” extraction were performed.

For deriving the scattered light background levels, we obtained guidance from saturated atomic lines with flat bottoms. We also verified that our equivalent widths agreed reasonably well with those measured by Spitzer, Cochran & Hirshfeld (1974). In some cases, we had to make adjustments of up to 20% in the background levels to make some lines agree with others.

3.2. Accurate Velocity Registration of H₂ Lines

To reduce the errors in radial velocities caused by image distortions, we found pairs of H₂ features that were near each other on the echelle spectrum format, but which came from different J levels. Lines on a single order that were separated by about 0.1 Å (or less) or lines on adjacent orders (or nearly so) with a very small horizontal separation were deemed to be suitable for this purpose. The identities of these combinations are given in the endnotes of Tables 2 and 3. We then measured the differences in radial velocity and used them to define the relative shifts of the absorptions from different J levels with respect to each other. The shifts averaged out to nearly 0 km s^{−1} for the features in both δ and ϵ Ori, with the largest single deviation being about 1 km s^{−1}. In using the line pairs to define the velocity offsets, our working assumption was that image distortions over very small scales were absent, and thus the offsets were identical for both lines.

To determine an absolute reference of the velocity scale, we compared the positions of the 5–0 R(0) and 5–0 R(1) lines to three prominent telluric features of O I out of excited fine-structure levels. These lines are rarely seen to arise from interstellar clouds, and thus they serve as excellent velocity calibration features in our spectra.

3.3. A Validation of f -values for some Weak Lines

Jenkins & Peimbert (1997) encountered some difficulty in obtaining consistent results for different combinations of lines of H₂ arising from the weakest members of the Lyman bands out of $J = 0, 1$ and 2 . It was possible that these inconsistencies could have arisen from either uncorrectable saturation effects, systematic errors in the background levels, errors in the adopted f -values, or some combination of the three. The amount of H₂ in the direction of δ Ori A is not very high. For this reason, the weak H₂ transitions should have very small corrections for saturation, which leads to an opportunity to check on the reasonableness in the relative f -values. This is an important check to make, since these lines provide the only means for us to measure the strongest parts of the features out of $J = 0, 1$ and 2 for ϵ Ori.

Figure 2 shows the curves of growth for weakest lines out of $J = 1$ and 2 in our spectrum of δ Ori A. Unfortunately, the weakest lines out of $J = 0$ were too weak to give meaningful information. To estimate the amount of possible saturation in the H₂ lines, we computed their expected behavior for a velocity profile that was identical to the superposition of components derived for Na I in front δ Ori A by Welty, Hobbs & Kulkarni (1994), based on their much higher resolution recordings of the D1 line. (There is no reason to expect the H₂ to exactly mimic Na I, but this is the best example that we can draw upon. We do not want to use our own H₂ data because there may be very narrow features that are not evident at our resolution.) The reasonably good correspondence between our measurements and the curves in the figure indicates that the adopted relative f -values from the theoretical calculations of Abgrall & Roueff (1989) are reasonably accurate.

3.4. Column Densities vs. Velocities

After correcting individual line velocity offsets (§3.2), we derived the apparent differential column densities per unit velocity for each transition given by the expression

$$N_a(v) = 3.768 \times 10^{14} \frac{\tau_a(v)}{f\lambda} \text{ cm}^{-2}(\text{km s}^{-1})^{-1} , \quad (1)$$

Fig. 2.— The observed strengths of weak H_2 features out of $J = 1$ (triangles) and 2 (diamonds), expressed in terms of $\log(W_\lambda/\lambda)$ in the spectrum of δ Ori A, against the published values of $\log(f\lambda)$ (Abgrall & Roueff 1989). The error bars show the 1σ uncertainties caused by noise and a 10% error in the background estimate [except for the recording of the 1-0 P(1) line, where the background uncertainty was larger]. The curves show the calculated shapes of the curve of growth for the lines, based on Na I absorptions observed by Welty et al. (1994). The horizontal placement of these curves are shifted to best match the points for $J = 1$ and 2.

where f is the transition’s f -value and λ is expressed in Å. The apparent absorption optical depth $\tau_a(v)$ is defined in terms of the continuum level I_0 and measured intensity $I(v)$ by the relation

$$\tau_a(v) = \ln \left(\frac{I_0}{I(v)} \right) . \quad (2)$$

For each J level, we consolidated the $N_a(v)$ ’s for different lines into a single composite profile with the technique devised by Jenkins & Peimbert (1997). Not all of the lines that were visible in the spectrum were included in the composite. Some were rejected because they had interference from other lines, were too close to the edge of an image, or fell below a threshold that we defined for the minimum acceptable signal-to-noise ratio. The lines that were chosen (except where noted) are listed in Tables 2 and 3.

For ϵ Ori, even the weakest lines out of $J = 0, 1$ and 2 were saturated. In the central portions of these lines, we implemented the correction technique developed by Jenkins (1996) to compensate for the error between the apparent optical depth $\tau_a(v)$ and a smoothed representation of the proper optical depth $\tau(v)$. The pairs of lines that were used in each case are identified in Table 3. The other lines for these three J levels were used to define the shoulders of the $N_a(v)$ distributions.

The usefulness of the correction technique is strongly driven by how well one knows the zero intensity level. If it is poorly known, there can be an ambiguity in the interpretation of lines that do not have $\tau_a(v)$ scaling in proportion to $f\lambda$. A poor scaling can arise either if the background levels are wrong or if the lines have unresolved, saturated substructures. Unfortunately, there are no strong atomic lines in the vicinity of the weakest H_2 lines. Thus, for these cases we must acknowledge the existence of background uncertainties and their possible influence on the accuracy of the corrections for saturated absorptions for $J = 0, 1$ or 2 in ϵ Ori. The increased errors are reflected in column 5 of Table 5.

Lines out of $J > 2$ for ϵ Ori and all of the H_2 lines in the spectrum of δ Ori A either showed good consistency in their $N_a(v)$ profiles from strong to weak lines, or they were so weak that the distortions caused by saturated sub-structures should not be a problem. Also, the background levels for these lines are probably more reliable than for those that we had to use for $J = 0, 1$ and 2 for ϵ Ori because there were nearby, saturated atomic lines.

^aAll transitions are in the $2p\sigma B^1\Sigma_u^+ \leftarrow X^1\Sigma_g^+$ Lyman band system, unless preceded with a “W” which refers to the $2p\pi C^1\Pi_u \leftarrow X^1\Sigma_g^+$ Werner bands.

^b $N(v)$ for the main part of the profile was determined using the pair of lines and the optical depth correction method of Jenkins (1996). Other lines were used only to define the low-level wings of the velocity profile.

^cThe 1–0 R(0) line is very near the 2–0 R(3) line 2 echelle orders away. These two lines were used to register lines out of $J = 0$ to those from $J = 3$, as described in §3.2.

^dThe 4–0 R(0) line is very near the 5–0 R(4) line in an adjacent echelle order. These two lines were used to register lines out of $J = 0$ to those from $J = 4$, as described in §3.2.

^eThe velocity scale for this line was forced to be consistent with the placement of the telluric O I* (1027.431 and 1040.943Å) and O I** (1041.688Å) lines at their computed heliocentric velocities at the time of observation. See §3.2 for details.

^fThe 5–0 R(0) line is very near the 4–0 P(1) line 3 echelle orders away. These two lines were used to register lines out of $J=0$ to those from $J = 1$, as described in §3.2.

^gThe proximity of the 7–0 R(0) and W 0–0 Q(3) lines to each other ($\Delta\lambda = 0.13\text{Å}$) enables an accurate registration of the velocities of the lines out of $J = 0$ to those out of $J = 3$.

^hThe 0–0 P(1) and 0–0 R(2) features are on top of each other ($\Delta\lambda = 0.06\text{Å}$), but a comparison of the left-hand component for the former with the right-hand one of the latter allows us to link the velocity scales of absorptions out of $J = 1$ and 2. Neither of these profiles were used in constructing the composite profiles.

ⁱNot used in building a composite profile.

^jThe 2–0 R(1) line is very near the 3–0 R(3) line 2 orders away. These two lines were used to register lines out of $J = 1$ to those from $J = 3$, as described in §3.2.

^kThe 5–0 R(2) line is very near the 5–0 P(3) line in an adjacent order. These two lines were used to register lines out of $J = 2$ to those with $J = 3$, as described in §3.2.

^lThe W 0–0 Q(2) line is very near the 8–0 R(3) line in an adjacent order. These two lines were used to register lines out of $J = 2$ with those from $J = 3$, as described in §3.2.

^mThis line was observed twice.

4. Results

4.1. Qualitative Conclusions

Figure 3 shows logarithmic depictions of the apparent column densities (from Eq. 1) for all observable J levels for the two stars. It is clear from the shapes of the profiles in Fig. 3 that our results agree qualitatively with the conclusions derived by Spitzer et al. (1974) from *Copernicus* data, refined by a more meticulous study by Spitzer & Morton (1976) in the case of δ Ori, that the general structures seen toward both δ and ϵ show some broadening with increasing J . For instance, the main peak in the spectrum of δ Ori A centered at 25 km s^{-1} is accompanied by a shoulder at more negative radial velocities that becomes more prominent with increasing J . The shape of the peak itself is invariant with J however [measured widths (FWHM) of linear representations of the profiles shown in Fig. 3 are 7, 6, 7 and 8.5 km s^{-1} for $J = 0 - 3$, respectively, with the higher result for $J = 3$ probably being attributable to the stronger contribution from the shoulder]. The broadening with increasing J is less clear for ϵ Ori. The most conspicuous effect here is the decrease in the apparent depth of the gap between the two peaks when going from $J = 0, 1, 2$ to $J = 3, 4, 5$. For the H_2 lines in the spectrum of ϵ Ori recorded by *Copernicus*, the two components are not resolved, but appear as a single peak with a slight asymmetry (Shull 1979).

The three Orion Belt stars seem to have in common a main peak centered at a velocity of approximately 25 km s^{-1} . It is strongest toward ϵ , of intermediate strength for ζ [compare our Fig. 3 with Figs. 2 – 6 of Jenkins & Peimbert (1997)], and weakest in the spectrum of δ . Maps of 21-cm emission over a velocity range $+18$ to $+26 \text{ km s}^{-1}$ ($+1$ to $+9 \text{ km s}^{-1}$ LSR) show a pronounced north-south ridge of atomic hydrogen to the east of ζ Ori A (Chromey, Elmegreen, & Elmegreen 1989; Green 1991). If the main H_2 peak were closely coupled with this atomic hydrogen, we would have expected ζ Ori to show the largest column density, ϵ an intermediate value, and δ the smallest. Instead, ϵ actually shows the most, with ζ being second and δ third.

At $+11 \text{ km s}^{-1}$ ϵ shows a peak that is almost as strong as its main peak at $+25 \text{ km s}^{-1}$, while for δ this peak is weaker and spread over a large range of velocities. H_2 at this velocity shows up very weakly in the spectrum of ζ [identified as Component 2 by Jenkins & Peimbert (1997)]. This behavior seems to agree with the 21-cm results: an isolated cloud of hydrogen, about 1 degree in diameter, is seen at the approximate location of ϵ in the maps of Chromey, et al. (1989) and Green & Padman (1993) at $v_{\text{LSR}} = -3$ to -8 km s^{-1} (i.e., consistent with our heliocentric velocity of $+11 \text{ km s}^{-1}$). Finally, the existence of a component at about -1 km s^{-1} seems to be unique to ζ , but we could not identify in the

Fig. 3.— Semilog plots of the apparent differential column densities $N_a(v)$ (defined in Eq. 1) for each J level of H_2 in the direction of δ Ori A (left column of panels) and ϵ Ori (right column). For $J = 0, 1$ and 2 toward ϵ Ori, we evaluated the strong, central portions of the profiles from the two weakest transitions using a procedure described by Jenkins (1996) for correcting for saturated, unresolved features inside the main peaks. The dotted lines show the outcome for the weakest line without this correction.

21-cm maps any distinctive atomic hydrogen cloud that was linked to it.

While the H_2 profiles toward δ and ϵ Ori show some changes in shape as the J values progress to higher values, there seems to be no manifestation of the distinctive broadening and shifts toward more negative velocities exhibited by the most negative velocity component [Component 1 of Jenkins & Peimbert (1997)] seen in the direction of ζ Ori A. Our original aim in this investigation was to study possible new examples of this phenomenon, but none were found. This conclusion is interesting in view of fact that these stars are separated by only about 10 pc in projection on the sky. As long as we are not being misled by the existence of a considerably larger separation longitudinally, our initial expectation was that the stellar winds from these stars probably create a single interstellar bubble that is common to all of them (Castor, McCray, & Weaver 1975; Weaver et al. 1977). Other factors being equal, it was natural to expect that the interactions of these winds with the ambient medium should be similar in all three cases.

4.2. Distribution of H_2 over Different J Levels

The logarithms of the column densities $\int N_a(v)dv$ over different velocity intervals and their errors are listed in Tables 4 and 5, along with results reported by Spitzer et al. (1974). For all J levels in both stars, the two investigations agree within their combined errors. The atomic hydrogen column densities toward these stars are given in Table 1. The fractions of H atoms bound into molecular form $2N(\text{H}_2)/[2N(\text{H}_2) + N(\text{H I})]$ are 7×10^{-6} for δ and 1.3×10^{-4} for ϵ .

Figure 4 shows a plot of $\log(N_J/g_J)$ vs. E_J/k for different components of the H_2 absorption observed toward δ and ϵ Ori, where N_J is the column density in level J , g_J is the degeneracy of this level, and E_J is its energy above the $J = 0$ level. One can use the Boltzmann equation to define an effective rotational temperature T_{rot} between two levels J and J'

$$T_{\text{rot}} = \frac{E_{J'} - E_J}{k \ln(10) [\log(N_J/g_J) - \log(N_{J'}/g_{J'})]} \quad (3)$$

which leads to the fact that T_{rot} is proportional to the negative inverse of the slope of a line joining the points for the respective levels in Fig. 4.

For ϵ Ori, both components show nearly identical relative populations, but they seem to exhibit two values for T_{rot} . One applies to the interval $J = 0 - 3$ and another is appropriate for $J = 3 - 5$. We have determined each by finding least-squares, linear fits to the points in Fig. 4, and the outcomes are stated near these trend lines. The abrupt change in slope usually signifies a transition from temperatures that are coupled to collisions at

^bApplies to the preceding three columns.

^cIncludes a correction for unresolved saturated absorptions, using the method of Jenkins (1996).

^dA value $\log N_5 = 13.32$ is given by Shull (1979).

Fig. 4.— The relationships between the column densities in different J levels, N_J , divided by their respective statistical weights, g_J (expressed in terms of the logarithm of the value in cm^{-2}) plotted against their energies E_J/k (expressed in K). The negative inverse slopes of the best fit lines indicate the rotational temperatures T_{rot} . The fits for ϵ Ori are to an average of both velocity components, since their behaviors are so similar.

low J to ones that are dominated by optical pumping at higher J . Another effect that may contribute to the relationship at low J is a diminution of the pumping rate at the lowest J levels caused by the pumping lines becoming optically deep.

The radiative decay rates at large J are so fast that collisions have a practically negligible effect. For this reason, to a reasonable approximation we can use the ratios N_4/N_3 and N_5/N_3 as indicators of the density of pumping radiation (when the radiation density increases, a large proportion of molecules in $J = 3$ are pumped to the upper electronic level before they have a chance to decay to $J = 1$ – see §V(a) of Spitzer & Morton (1976) for a more complete discussion and representative examples). When we compare our ratios for ϵ Ori with models presented in Table 5 of Spitzer & Morton (1976), we conclude that the pumping rate $\beta = 3 - 10 \times 10^{-9}\text{s}^{-1}$ for Component 1 and $1 - 3 \times 10^{-9}\text{s}^{-1}$ for Component 2. For comparison, Jura (1974) calculated that $\beta = 5 \times 10^{-10}\text{s}^{-1}$ in the general vicinity of the Sun. The elevation in β for H_2 in front of ϵ Ori seems consistent with what one would expect for gas that is in the general vicinity of the association but not especially close to one of the bright, early-type stars.

We have less complete information on the distribution with J for δ Ori A because the overall column density of H_2 is lower. Since our values for N_J are nearly the same as those of Spitzer & Morton (1976), we adopt their interpretation for the conditions that lead to the observed relative populations. Spitzer & Morton found that for their Component 3 of H_2 for δ Ori A, which approximately corresponds to our main peak, $\beta = 2 \times 10^{-10}\text{s}^{-1}$ for $J = 0$ and 1, but $\beta = 5 \times 10^{-10}\text{s}^{-1}$ for $J = 2$. This seems to indicate that the gas in the main component is rather distant from the Orion stars. The lower pumping rate in the lowest J levels probably arises from the diminution of flux from distant stars by molecular complexes unrelated to the one seen toward δ Ori A, since in our spectrum only the strongest lines, such as those the Werner 1–0 Q(1) and 2–0 Q(1) transitions, have central optical depths appreciably greater than about 2. The suggested remoteness for this component of H_2 from the Orion association is an unexpected conclusion when one considers the fact that its velocity is very similar to one of the main components in front of ϵ Ori (and also ζ Ori A). Perhaps the molecules in front of δ Ori A are heavily shielded from the pumping radiation by other parts of the same gas complex in the vicinity of the Orion association.

For the shoulder component toward δ Ori A, the upper limit for $J_5/J_3 < 0.15$ found by combining our results with those of Spitzer et al. (1974) indicates that $\beta < 4 \times 10^{-9}\text{s}^{-1}$. In the limit of a low density, the high rotation temperature $T_{\text{rot}} = 850\text{K}$ for $J = 0 - 3$ would be consistent with a considerably larger value of β , so perhaps the local kinetic temperature is about 850K and the density is large enough to have collisions couple T_{rot} to this temperature.

5. Interpretation

We turn now to the question of what we can learn from the absence of the broadening and velocity shifts in the spectra of δ and ϵ Ori that Jenkins & Peimbert (1997) found in the most negative velocity H_2 feature for ζ Ori A. In particular, are there other differences between the two stars featured here and ζ Ori A that are noteworthy and might give us further insights on the phenomenon? Does this information support or refute the interpretation that it arises from H_2 forming in a cooling zone behind a bow shock, one that could be created by the collision of a gas flow coming toward us and a foreground obstruction, as suggested by Jenkins & Peimbert (1997)?

In addressing the question just posed, we examined two types of evidence. First, we searched for differences revealed by other spectral features for these stars (§5.1). Second, we looked for relationships of the stars with structural features of the interstellar medium detected by other means (§5.2). In both cases, we noted certain properties that set ζ Ori A apart from δ and ϵ Ori.

5.1. Singly Ionized Gas at High Negative Velocities

Figures 5 and 6 show IMAPS recordings of the strong resonance lines of the singly ionized forms of C and N, respectively, for the three Orion Belt stars. The most striking difference that sets ζ apart from δ and ϵ is the absorption from material that is moving at a radial velocity that ranges between -100 and -70 km s^{-1} . In the spectrum of ζ Ori A, similar components at these velocities are seen in C III, N III, Si III and S III (Cowie, Songaila, & York 1979) and Al III (medium-resolution GHRS spectrum in the *HST* archive⁶), but are not visible in the strong transitions of O I and N I. The interpretation of Jenkins & Peimbert (1997) regards this as the upstream material that feeds the shock front that is responsible for the H_2 component at -1 km s^{-1} which shows the unusual behavior with increasing J . The correlation of the presence or absence of the high velocity gas with the phenomenon noted by Jenkins & Peimbert seems to favor their shock interpretation over completely unrelated alternatives.

⁶Exposure identification: Z165040DM.

Fig. 5.— Fluxes in the vicinity of the C II transition at $1036.337\text{\AA}$ for δ , ϵ and ζ Ori, depicted on a scale of heliocentric radial velocities for this transition.

Fig. 6.— Plots similar to those of Fig. 5 that apply to the N II transition at 1083.990 Å.

5.2. Interstellar Gas Structures

The interstellar material in the general vicinity of the Orion OB1 association contains a number of well-studied gas complexes and prominent emission regions [see Goudis (1982) for a detailed summary]. The lines of sight to ϵ and δ seem unremarkable, but that toward ζ Ori A points in a direction that is very close to the densest concentration of material within the Orion B molecular cloud complex. This cloud has a large visual extinction and appears as entry number 1630 in the catalog of dark nebulae compiled by Lynds (1962). It has a significant internal density, and it contains a large number of very young, but highly obscured stars (Strom, Strom, & Vrba 1976). The striking difference between the direction toward ζ and those toward the other two stars is shown in a map of thermal emission from dust (Schlegel, Finkbeiner, & Davis 1998) recorded by the IRAS satellite, depicted in Fig. 7, and likewise in maps of CO emission (Kutner et al. 1977; Maddalena et al. 1986). Maps of 21-cm emission in this region of Orion show no indication of this strong contrast (Chromey, Elmegreen, & Elmegreen 1989; Green 1991; Green & Padman 1993), probably because the emission from this cold, highly condensed cloud is very badly saturated.

Could Lynds 1630 and its bright edge IC 434 (see Fig. 8) on the side toward ζ and σ Ori (Pottasch 1956) be the obstruction proposed by Jenkins & Peimbert (1997) that is needed to create a stationary bow shock in the stellar wind material? The plausibility of this idea very much depends on whether or not Lynds 1630 is in front of or behind ζ Ori.

At first glance, one might suppose that the cloud must be in front, since the main body of the cloud appears much darker in $H\alpha$ emission than the edge toward ζ Ori. Also, the existence of the Horsehead nebula as a dark silhouette against the $H\alpha$ emission is an additional clue, although there is a reasonable chance that the background excitation at this particular location could arise from radiation from σ Ori (which might be more distant) rather than ζ Ori. The bright, foreground H II region NGC 2024 [also known as the Orion B radio source (Barnes et al. 1989; van der Werf et al. 1993)] is powered by UV radiation from one or more highly obscured star(s) embedded within it, not by ζ Ori (Grasdelen 1974).

On closer inspection, however, we conclude that the indications offered by the structure of the most easily evident $H\alpha$ emission could be misleading. If we disregard the very bright patch of $H\alpha$ emission associated with the edges of the Lynds 1630 cloud and consider the fainter, more broadly distributed emission in the general region, a different picture emerges. Nearly all of the volume inside Barnard’s Loop (Pickering 1890; Barnard 1894) is filled with a faint glow created by the ionizing radiation from the Orion association (Sivan 1974). Fig. 8 shows a contour map of $H\alpha$ emission in the vicinity of ζ and ϵ Ori, well inside the perimeter of Barnard’s Loop. This map was constructed from the survey of

Fig. 7.— Locations of δ , ϵ and ζ Ori with respect to diffuse emission by dust at $100\mu\text{m}$ recorded by IRAS, but cleaned by Schlegel, Finkbeiner & Davis (1998) and then renormalized to represent $E(B - V)$, using information about grain temperatures derived from DIRBE observations at longer wavelengths. The darknesses in this depiction are proportional to the logarithm of this computed color excess. The dense cloud near ζ is Lynds 1630. Values of the computed $E(B - V)$ at the positions of δ , ϵ and ζ in this map equal 0.25, 0.30 and 5.14, respectively. For δ and ϵ Ori, their actual values of $E(B - V)$ of 0.09 and 0.05 indicate that more than half of the dust emission originates from material behind the stars. The locations of B-type stars whose IUE spectra were examined by Shore (1982) and Sonneborn, et al. (1988) are indicated: those with UV absorption features at velocities equal to or more negative than -50 km s^{-1} are shown with asterisks, while those without such features are shown with crosses. The inset shows a HIRES processing (beam width $< 1'$ FWHM) of the 100μ IRAS flux in the immediate vicinity of ζ Ori.

Fig. 8.— A contour map of the intensity of H α emission in the general vicinity of the dense cloud Lynds 1630, recorded by Gaustad et al. (1999). The bright north-south ridge of emission is IC 434, and the region of high obscuration in Lynds 1630 is just to the east of it. The highest contour levels have been clipped. Fluxes depicted here are only relative, since the sensitivity to H α emission and the zero offset caused by geocoronal H α emission have not yet been determined.

Gaustad et al. (1999)⁷, and it clearly shows that the brightness level at the locations where there is significant obscuration from the cloud (but somewhat removed from NGC 2024) is comparable to the flux from directions approximately midway between ζ and ϵ Ori, well beyond the cloud’s edge to the northwest. [An earlier study of H α emission in this vicinity by Vidal (1980) also shows this result, but not as clearly.] On the one hand, this finding suggests that the Lynds 1630 cloud is behind the Belt Stars, if they were responsible for ionizing hydrogen and producing H α emission in front of the cloud or right on the cloud’s front edge. On the other hand, we could argue that one or more stars other than ζ Ori, such as σ Ori (spectral type O9.5 V), are responsible for most of the emission and are closer to us than ζ Ori. Unfortunately, spectroscopic or Hipparcos parallaxes are not accurate enough to resolve this issue. If, by contrast, we had found that the H α emission were darker in front of Lynds 1630 than in directions close to ϵ Ori, we might have had a more positive indication that the cloud was well in front of the Belt Stars and appears as a silhouette.

Other evidence that disfavors Lynds 1630 being in the foreground, but again not conclusively, arises from the distribution of dust shown in Fig. 7. The amount of infrared 100μ emission from the cloud’s dust in the exact direction of ζ Ori leads to an expected B–V color excess that seems to be far greater than the star’s actual $E(B - V) = 0.05$. A HIRES processing⁸ of the 100μ image (see inset of Fig. 7) shows that we are not being misled by the smoothing in the representation generated by Schlegel, et al. (1998) combined with the star’s proximity to a sharp edge of the cloud. Nevertheless, the gas could be clumpy on scales even smaller than the HIRES picture, and the line of sight to ζ Ori could miss the clumps.

The indications that Lynds 1630 may be behind ζ Ori cast doubt on the interpretation that it is a conspicuous barrier for the stellar wind from the star. Nevertheless, we still should not overlook the possibility that its presence in the same general direction of the star may still be significant. The cloud contains very dense concentrations of molecular material, as revealed by high-resolution maps of molecular emission by Lada, Bally & Stark (1991) (CS), Bally, Langer & Liu (1991) (^{13}CO), and Stark & Bally (1982) (^{12}CO). It is often true that clouds containing compact molecular regions are sites of star formation, and the Orion B cloud is no exception (Bence & Padman 1996; Chernin 1996; Launhardt et al. 1996; Zinnecker, McCaughrean, & Rayner 1996; Sandell et al. 1999). One product of star

⁷Preliminary data in digital form were provided by Dr. J. Gaustad in advance of publication of the actual results.

⁸The HIRES processing was performed at the Infrared Processing and Analysis Center, using the “Maximum Correlation Method” to create images with a high angular resolution (Aumann, Fowler, & Melnyk 1990).

formation is the creation of high speed, bipolar flows of gas (Bally 1982; Genzel & Downes 1982; Königl 1996) with velocities that have about the same magnitude as the component in front of ζ Ori A shown in §5.1 (Eisloffel 1996; Hirth, Mundt, & Solf 1996). If such flows penetrate beyond the edge of the dense cloud and into a low-density medium, they could extend over large distances (Reipurth, Bally, & Devine 1997), perhaps even farther than the remote, multiple shocks (Bence & Padman 1996) that can be detected in emission. Still another possibility is that the high speed gas arises from the breakout of material from an embedded, recently formed H II region (Tenorio-Tagle 1979; Sandford, Whitaker, & Klein 1982; Subrahmanyam et al. 1997).

In §5.1 we pointed out that δ and ϵ Ori do not show gas at high negative velocities, while ζ Ori does. We can investigate this phenomenon further by examining the outcome of a survey of UV absorption features in B-type stars carried out by Shore (1982) and Sonneborn, et al. (1988). In Fig. 7 we indicate the positions of these stars and with different symbols show whether they do (*) or do not (+) exhibit features from singly-charged ions at velocities equal to or more negative than -50 km s^{-1} . It seems clear that stars in the vicinity of Lynds 1630 usually show the high-velocity features, while those that are somewhat removed in a lateral direction, such as the targets in the general vicinity of δ and ϵ Ori, do not. This outcome suggests the possibility that the dense molecular cloud may be the source of high velocity gas. While this may be so, we should not overlook the fact that high velocity features are seen elsewhere in the Orion region (Cohn & York 1977; Cowie, Songaila, & York 1979), with some of them at locations outside the coverage of Fig. 7. With this in mind, we could equally well propose that a more general, coherent expansion of gas from a larger scale event is taking place. In this picture, the appearances of high velocity features in Fig. 7 could arise from just random fragments of enhanced density in the expanding material.

6. Concluding Remarks

In studying the spectra of δ and ϵ Ori, we had high expectations of finding duplications of the unusual findings of Jenkins & Peimbert (1997) for one of the H_2 components toward ζ Ori A. They reported that the profile became broader and shifted toward more negative radial velocities as the rotational excitation increased from $J = 0$ to 5. Our optimism about seeing more examples of this phenomenon was based on the premise that, in Jenkins & Peimbert’s interpretation of a bow shock as its source, the stellar wind that may have created this shock front was probably a composite phenomenon common to all three stars in the Orion Belt. The apparent lack of this effect for δ and ϵ Ori deprives us of the chance

to see additional manifestations of it, but opens the way for us to examine circumstantial evidence that could give us more insight on the validity of the shock interpretation.

Aside from not showing the strange behavior of H_2 , δ and ϵ Ori differ from ζ Ori in two other respects that could have a bearing on the shock interpretation. First, ζ shows absorption by singly and doubly ionized species at a velocity of about -90 km s^{-1} , while the others do not. This high velocity material was a good candidate for the upstream gas that could have created the bow shock. Second, in projection ζ Ori is very near the edge of the dense cloud Lynds 1630, an accumulation of gas that exhibits a bright edge of ionized material (IC 434) on the side towards ζ Ori and holds within it many compact regions of star formation. The sight lines to δ and ϵ Ori are, by contrast, unremarkable.

The real source of the gas at -90 km s^{-1} that is seen in the spectrum of ζ Ori is uncertain. It may be some byproduct of the winds from the stars, but it is not easy to understand why similar components are not seen toward δ and ϵ Ori. An interesting alternative is the possibility that the -90 km s^{-1} component has nothing to do with stellar winds from the Belt stars. The complex of very dense gas near the ζ Ori line of sight is known for its plentiful star forming regions. Such regions typically discharge gas at high velocities, starting with flows that are highly collimated. Perhaps one such flow could escape from its gas envelope and be responsible for the high velocity component that shows up for ζ Ori in Figs. 5 and 6. A well-directed flow could provide a reasonable way to explain the absence in the spectra of δ and ϵ Ori of any feature analogous to the -90 km s^{-1} component exhibited by ζ Ori A.

New insights on the problem discussed in this paper may arise from observations by the Far Ultraviolet Spectroscopic Explorer (FUSE), which has the capability of examining a very much broader sample of cases in its lifetime. However its lower wavelength resolution will make it harder to study the detailed structures in the H_2 profiles, and productive research in this area may require the existence of even more extreme cases of profile variations with J than those shown toward ζ Ori A.

The observations reported in this paper were recorded by IMAPS during its second orbital flight, which was carried out on the ORFEUS-SPAS II mission in 1996. This effort was a joint undertaking of the US and German space agencies, NASA and DARA. The successful execution of our observations was the product of efforts over many years by engineering teams at Princeton University Observatory, Ball Aerospace Systems Group (the industrial subcontractor for the IMAPS instrument) and Daimler-Benz Aerospace (the German firm that built the ASTRO-SPAS spacecraft and conducted mission operations). Contributions to the success of IMAPS also came from the generous efforts by members of

the Optics Branch of the NASA Goddard Space Flight Center (grating coatings and testing) and from O. H. W. Siegmund and S. R. Jelinsky at the Berkeley Space Sciences Laboratory (deposition of the photocathode material). We are grateful B. T. Draine for his comments on an early draft of the paper and to J. Gaustad for supplying the digital representation of the $H\alpha$ image that was the basis of our Fig. 8. This research was supported by NASA grant NAG5–616 to Princeton University.
